20. Abstract (Concluded) activated sludge systems for semi-continuous addition of waste containing the fuels and for slug doses from accidental spills.

It was concluded from the continuous feed studies that the three hydrazines could cause significant deterioration of an activated sludge plant if the concentration in the influent exceeded a few mg/l. For an aeration basin with a common hydraulic detention time of 9 hours, the efficiency of organic removal is seriously degraded when the influent concentration of HZ exceeds 10 mg/l. For UDMH and MMH this total failure results at concentrations of approximately 8 mg/l and 5 mg/l, respectively. Interpolating from these continuous feed studies, the "no effect level" would be approximately 1 mg/l for HZ and 2 mg/l for MMH and UDMH.

The influence of the hydrazines on nitrogen speciation of the sewage treatment plant effluent is more pronounced than that found for organic carbon oxidation. Inhibition of nitrification occurred at concentrations above 0.5 mg/l for MMH and 1 mg/l for the other fuels.

Only at the lowest HZ concentrations tested (<1 mg/l) was the effluent fuel concentration below detection limits, and for MMH and UDMH the maximum removal efficiency observed was 89 percent and 96 percent, respectively. Other AF-sponsored studies on the effect of these fuels on algae have established "no effect" concentrations of less than 0.001 mg/l for MMH and 1.56 mg/l for UDMH.

For slug doses (because of the short exposure) the effect of transient high fuel concentrations would be less than for a continuous exposure. The concentrations found to cause no significant effect on sewage treatment efficiency are 74 mg/l for UDMH, 44 mg/l for HZ, and ~32 mg/l for MMH. Ammonia oxidation was effected for all three fuels at the lowest concentration tested (~25 mg/l). Recovery times for the highest concentrations tested (~250 mg/l) are in the range of 2 to 5 days.

Extensive background information is presented on the theory of dispersed growth bacterial systems.

PREFACE

This report summarizes work performed in accordance with Technical Need (TN) SAMSO-AFCEEDO-1302-76-49, "Disposal of Hydrazine Fuels Hazardous Waste," under program element 63723F, JON 21037W84. The project officers were Major Michael G. MacNaughton and Capt Jay A. Farmwald of the Civil and Environmental Engineering Development Office (CEEDO). Effective 1 March 1979, CEEDO was inactivated and became the Engineering and Services Laboratory (ESL), a directorate of the Air Force Engineering and Services Center, Tyndall Air Force Base, Florida 32403. This work was begun in June 1977 and was completed in July 1979.

This report has been reviewed by the Public Affairs Office and is releasable to the National Technical Information Service (NTIS). At NTIS it will be available to the general public including foreign nations.

This technical report has been reviewed and is approved for publication.

SECTION I

INTRODUCTION

1. BACKGROUND

The Air Force (AF) procures amine based hydrazine fuels for use in Titan II and III, Minuteman III, Bomarc and F-16 systems and is also responsible for the procurement, storage, and transport of such fuels in support of the National Aeronautics and Space Administration (NASA) and AF Space Shuttle Program. This results in an annual movement of approximately 2.36 kilograms (5.2 million pounds) of neat hydrazine (HZ), monomethylhydrazine (MMH), unsymmetricaldimethylhydrazine (UDMH), and Aerozine 50 (1:1 HZ:UDMH). Within private industry significant quantities of neat hydrazine are used as plastic blowing agents, anticorrosion agents for boiler waters, and growth inhibitors. MMH and UDMH are not widely used outside of NASA and the Department of Defense (DOD). The AF problem with respect to neat hydrazine is complicated by its use in the Emergency Power Unit (EPU) on the new F-16 aircraft which will be deployed worldwide. The EPU on the F-16 contains 24.6 liters (6.5 gallons) of a 70-percent aqueous hydrazine solution, and potential small spills during maintenance and handling of the unit require simple and effective cleanup procedures.

Documenting the ability of conventional biological waste treatment facilities to assimilate low concentration hydrazine wastes on a semi-continuous flow basis and/or slug loads resulting from transportation/operational spill situations would greatly simplify the development of preferred neutralization methodologies in single event scenarios. To evaluate the assimilative capacities of such domestic treatment systems, this research was developed to investigate both activated sludge and trickling filter unit processes. This report will summarize data on the effects of HZ, MMH, and UDMH in conventional activated sludge systems.

2. SCOPE

Using bench scale continuous flow recycle reactors a series of experiments were conducted to accomplish the following:

- Establish control parameters favoring the oxidation of both carbonaceous matter and ammonia (nitrification) for a supplemented primary effluent.
- Evaluate treatment efficiency under the selected operating conditions as a function of various continuous flow missile fuel concentrations.
- Document the effects of shock loadings under the selected conditions and monitor process recovery.

These data will serve as a basis for comparison with alternative physical/chemical treatment technologies in formulating AF contingency plans and should also prove useful in impact assessment exercises.

SECTION II

THEORY/BACKGROUND

1. DISPERSED GROWTH SYSTEMS

a. Substrate Utilization: The kinetics of soluble substrate utilization by dispersed bacterial populations are a function of the limiting substrate and microorganism concentrations. A relationship similar to that derived empirically by Monod (Reference 12) has been proposed for such systems (Reference 5).

$$\frac{ds}{dt} = \frac{kS X_a}{K_s + S} \quad (1)$$

$\frac{ds}{dt}$ = Substrate utilization rate per unit volume (mass/
volume - time).

k = Maximum rate of substrate utilization per unit weight
of microorganisms - at high substrate concentrations
(time⁻¹).

S = Limiting substrate concentration surrounding the micro-
organisms (mass/volume).

K_s = Half velocity coefficient (mass/volume).

X_a = Microorganism concentration (mass/volume).

Graphically, Equation (1) may be represented as shown in Figure 1. Inherent in this model is the assumption that only one substrate is limiting and that this substrate is both soluble and biodegradable.

Figure 1. Specific Substrate Utilization as a Function of Substrate Concentration, Monod Plot

b. Bacterial Growth: The empirical equation for bacterial growth (Reference 13) is:

$$\frac{dX_a}{dt} = Y \frac{ds}{dt} - bX_a \quad (2)$$

$\frac{dX_a}{dt}$ = net growth rate of microorganisms per unit volume (mass/volume-time).

Y = maximum yield coefficient (mass/mass).

b = microorganism decay coefficient (time⁻¹).

Equation (2) may be rearranged to:

$$\frac{\frac{dX_a}{dt}}{X_a} = Y \frac{\frac{ds}{dt}}{X_a} - b \quad (3)$$

On a finite mass and time basis where M refers to a definite mass of microorganisms (Reference 4):

$$\frac{(\Delta X_a / \Delta t)_M}{(X_a)_M} = Y \frac{(\Delta S / \Delta t)_M}{(X_a)_M} - b \quad (4)$$

c. Definitions: Using the above relationships, many useful parameters have been defined (References 4, 5).

(1) Net Specific Growth Rate: (μ)

$$\mu = \frac{(\Delta X_a / \Delta t)_M}{(X_a)_M} \quad (5)$$

Substituting Equation (1) into (3) and using Equations (4) and (5) we may further show that:

$$\mu = \frac{YkS}{K_s + S} - b \quad (6)$$

When $b = 0$ and $S \gg K_s$, μ_{\max} can be defined:

$$\mu_{\max} = Yk \quad (7)$$

(2) Mean Cell Residence Time: (θ_c)

$$\theta_c = \frac{1}{\mu} \quad (8)$$

Equations (5) and (8) result in Equation (9).

$$\theta_c = \frac{(X_a)_M}{(\Delta X_a / \Delta t)_M} \quad (9)$$

(3) Specific Utilization: (U)

$$U = \frac{(\Delta S / \Delta t)_M}{(X_a)_M} \quad (10)$$

d. Complete Mix - Cellular Recycle :

Figure 2 illustrates this classical treatment system which employs solids (cellular) recirculation in order to make θ_c independent of the hydraulic detention time (θ). However, as pointed out by Lawrence (Reference 5), θ_c cannot be varied completely independent of θ due to the practical limitations imposed by the settling characteristics of the biomass.

In developing relationships for complete mix recycle systems, several assumptions apply:

- Waste stabilization occurs only in the aeration basin (conservative assumption).
- Instantaneous and complete mixing occurs in the aeration basin.
- The total active biological mass in the system is equal to the biological mass in the aeration basin, i.e., the clarifier simply serves as a source of biomass through constant and continuous recycle.
- $S^e = S$

NOTE : WHEN INTENTIONAL WASTING IS ACCOMPLISHED FROM THE
AERATION BASIN $X^w = X$ AND $Q^0 = Q^0 - Q^w$

Figure 2. Complete Mixed Reactor with Cellular Recycle

(1) Substrate: The effluent substrate concentration, S^e , (that soluble fraction of the influent waste escaping treatment) for a system operating under constant environmental conditions and influent characteristics may be found by combining Equations (6) and (8) (Reference 5).

$$S = \frac{K_s (1+b \theta_c)}{\theta_c (Yk-b)-1} \quad (11)$$

Thus, for a given microbial population with specified substrate utilization and growth coefficients, treatment efficiency at steady state is a function of the mean cell residence time.

(2) Biomass: A relationship for the steady state microorganism concentration in the aeration basin may be derived from a mass balance on the substrate through the system. Under steady state conditions the substrate concentration in the aeration basin is constant, therefore:

Mass rate of substrate in + Mass Rate of substrate utilization = Mass Rate of substrate out

$$Q^o S^o + V \frac{ds}{dt} = (Q^o - Q^w) S^e + Q^w S \quad (12)$$

Recalling that $S^e = S$ and using Equations (3) and (5), it can be shown that:

$$X_a = \frac{\theta_c}{\theta} \frac{Y(S^o - S)}{1 + b \theta_c} \quad (13)$$

(3) Mean Cell Residence Time: Similarly, a mass balance for the microbial mass in the treatment system may be formulated. Under steady state conditions the organism concentration in the aeration basin is constant:

Mass rate of organisms in + Mass Rate of organism growth = Mass Rate of organisms out

$$Q^o X_a^o + \frac{V dX_a}{dt} = (Q^o - Q^w) X_a^e + Q^w X_a^w \quad (14)$$

Assuming that wasting is accomplished directly from the aeration basin, substitutions involving Equations (1), (2), (6), and (8) yield the following expression for θ_c :

$$\theta_c = \frac{V X_a}{(Q^o - Q^w) X_a^e + Q^w X_a^w - Q^o X_a^o} \quad (15)$$

Under steady state conditions the growth rate, $\Delta X/\Delta t$, is constant and represents the mass of organisms which must be wasted $(Q^o - Q^w) X_a^e + Q^w X_a^w$ to maintain a constant cell residence time. Because the net specific growth rate, μ , is derived from the substrate utilization and bacterial growth relationships, the implication is that θ_c , as defined by Equation

(15), applies only to those active organisms grown in the reactor. This, then, accounts for the $Q^O X_a^O$ term which must be subtracted as derived in the mass balance. In continuous flow activated sludge treatment systems a process control parameter which accurately describes the total system microbial mass is of interest. For this reason the operational definition for θ_c has most often been defined (Reference 5) as:

$$\theta_c = \frac{X_a V}{Q^e X_a^e + Q^w X_a^w} \quad (16)$$

Again, when wasting is accomplished from the aeration basin $Q^e = Q^O - Q^w$ and $X_a^w = X_a$.

(4) θ_c^m : There exists a minimum cell residence time below which active cells will be washed out of the system at a rate which exceeds their growth rate. When this occurs $S^O = S^e$, thus, from Equation (6):

$$(\theta_c^m)^{-1} = \frac{YkS^O}{K_s + S^O} - b \quad (17)$$

(5) Sludge for Disposal: From Equation (16) it is clear that the worst case with respect to excess sludge for disposal occurs when clarification efficiency is a maximum, i.e., $X^e = 0$. If P_x equals sludge for disposal in mass/time units, then:

$$P_x = Q^w X^w = \frac{VX}{\theta_c} \quad (18)$$

(6) Suspended Solids Balance: As described by Christensen (Reference 14), there are two different kinds of suspended solids commonly recognized: (1) the inorganic portion X_{in} , and (2) the organic portion X_v , generally termed volatile suspended solids:

$$X = X_{in} + X_v \quad (19)$$

where X represents total suspended solids. Further, X_v is considered to consist of four different organic fractions: (1) biodegradable suspended solids, X_d ; (2) refractory suspended solids, X_r ; (3) active organisms, X_a ; and (4) inert organism remains after cellular decay, X_i .

Because X or X_v is most often used as a measure of X_a the relationship between θ_c and the component fractions in X or X_v is of interest. If one assumes that the fraction of a particular suspended solids component in the effluent and waste stream is the same as its proportion in the reactor:

$$\theta_c = \frac{X_a V}{Q^e X_a^e + Q^w X_a^w} = \frac{X_j V}{Q^e X_j^e + Q^w X_j^w} \quad (20)$$

where j can equal in , a , i , d , or r . For the case when X_a^O and $X_i^O = 0$ and further assuming that X_d^O degradation is proportional to S^O

degradation, a mass balance on each of the suspended solids components will lead to an expression for X_v or X as a function of θ_c and θ , given constant environmental and influent waste conditions. The term f_d represents the fraction of an active organism which is biodegradable.

$$X_v = \frac{\theta_c}{\theta} \left(X_r^o + \frac{S}{S^o} X_d^o + \frac{Y(S^o - S)}{1 + b \theta_c} (1 + (1 - f_d)b \theta_c) \right) \quad (21)$$

and;

$$X = \frac{\theta_c}{\theta} X_{in}^o + X_v \quad (22)$$

Equation (21) is the fundamental design equation for complete mix suspended growth systems with or without cellular recycle while Equation (22) describes the operational solids retention time (SRT) used as the process control parameter.

$$SRT = \frac{\theta_c}{\theta} = \frac{XV}{Q^e X^e + Q^w X^w} \quad (23)$$

2. HYDRAZINES AS PROCESS INHIBITORS

To date, very little research has been conducted on the effects of hydrazines in biological waste treatment systems. Tomlinson, Boon, and Tratman (Reference 15) conducted batch-screening tests on nitrifying activated sludge at various concentrations of neat hydrazine. They found that a concentration of 64 milligrams per liter (mg/l) caused a 75-percent inhibition of ammonia oxidation and 48 mg/l resulted in 75-percent inhibition of nitrite oxidation. That hydrazine was more toxic to Nitrobacter sp. than Nitrosomonas sp. in activated sludge was in general agreement with Meyerhof (Reference 16) who studied pure cultures of Nitrosomonas sp. and found 20-percent inhibition of ammonia oxidation at 32 mg/l.

Yoshida and Alexander (Reference 17) used neat hydrazine as a selective inhibitor in their studies with Nitrosomonas europaea to show that hydroxylamine is an intermediate in the conversion of ammonia to nitrite. They reported that pure cultures exposed to 32 mg/l immediately ceased nitrite formation, but the rate of nitrite generation at 3.2 mg/l was still appreciable. Ammonium oxidation seemed to proceed even in the presence of 320 mg/l hydrazine, as evidenced by an accumulation of hydroxylamine. Verstraete and Alexander (Reference 21) in their work on heterotrophic nitrification found that the growth of Arthrobacter sp. was inhibited at 32 mg/l hydrazine but observed negligible effects at 3.2 mg/l. Tomlinson concluded that concentrations in this range may not actually cause problems in treatment plants because (1) the nitrifying bacteria may acclimate with time, and (2) hydrazine may be destroyed, in part, by any heterotrophic population present. His recommendations included investigations into the feasibility of pretreating such industrial wastes in a high rate trickling filter or activated sludge process before attempting nitrification. To date, this assumption has not been verified. Currently there is no literature available on the effects of MMH or UDMH on either pure cultures or activated sludges.

SECTION III EXPERIMENTAL METHODS AND MATERIALS

1. SUBSTRATE BASE

Throughout this investigation, primary effluent from the Tyndall Air Force Base (AFB) sewage treatment plant (STP) (Figure 3), was used as the raw feed. The Tyndall AFB facility, which treats 3.0 to 6.0 million liters (0.8 to 1.6 million gallons) of combined domestic and industrial wastewater per day, employs two single-stage trickling filters for secondary waste stabilization. Each rock packed filter is subjected to hydraulic loadings which range from 7.4 to 14.7 thousand liters/square meter/day (7.9 to 15.8 million gallons/Acre/DAY) (including 1:1 recirculation), the variation being a function of seasonal precipitation. The average organic loading is 16 Kg Biochemical Oxygen Demand (BOD)/cubic meter (M³)/Day (23.2 lb BOD_L/1000 ft³/DAY) per filter.

Characterization of the raw feed solution was undertaken to aid in designing the experiment and in an effort to quantify supplemental requirements. Analytical procedures, as outlined in Section III, paragraph 6 of this report, produced the data summarized in Table 1. The values represent an average of numerous data points collected over several months during the early stages of the study when system familiarization and troubleshooting runs were being made. From these data it was decided to enrich the raw feed by elevating the Chemical Oxygen Demand (COD) to 320 mg/l with Carnation Slender®. The ingredients, as computed from data supplied by the manufacturer, are itemized in Table 2. Stoichiometric relationships were then developed which were used to predict relevant nitrogen/oxygen requirements and indirectly estimate phosphorous and alkalinity demands. Based on these results, the enriched feed could be supplemented to insure the final feed solution fit the experimental design.

2. SUPPLEMENTAL REQUIREMENTS

McCarty (Reference 6) has suggested that stoichiometric equations may be written for bacterially mediated reactions. This procedure establishes molar coefficients which may be used to predict electron acceptor utilization, cellular yield, and supplemental requirements. Such an analysis was performed on the enriched feed solution used in this study. The procedure is outlined in Appendix A. The supplemental nitrogen, phosphorous, oxygen, and alkalinity requirements derived from these calculations are discussed below.

a. Nitrogen(N): Calculations indicated that 19.2 mg/l N would be required for heterotrophic synthesis. Based on the empirical formulations derived in Appendix A, it can be shown that the total organic-N available is 16.0 mg/l. In addition, the raw feed solution contains 12.7 mg/l inorganic-N ($\text{NH}_3\text{-N}$). Obviously there will be approximately 9.5 mg/l-N remaining which should be available for nitrification. In an effort to insure nitrogen was not limiting and to increase the amount available for nitrification, 4.7 mg/l urea-N was added to the enriched feed.

b. Phosphorous(P): To insure phosphorous was not limiting, the enriched primary effluent was supplemented with 5.2 mg/l $\text{PO}_4\text{-P}$. This raised the total available phosphorous to 11.9 mg/l compared to the demand of 3.0 mg/l.

c. Oxygen(O_2): To insure an excess of dissolved oxygen (DO), humidified air was sparged through the mixed liquor at a rate of 4 liters/minute. Based on an air density of 1.2 grams (gm)/liter under the experimental conditions (1 atmosphere, 20 degrees celsius ($^{\circ}\text{C}$) and noting that air is 21 percent oxygen by weight, it can be shown that approximately 145 gm O_2 /day were made available to the system. Assuming a conservative oxygen transfer efficiency of 5 percent (Reference 18), the calculated absorptive capacity is 7.2 gm O_2 /day, or a 30-percent excess. Periodic checks on the mixed liquor to confirm a DO above 5 mg/l would later insure that oxygen was not limiting during the investigation.

d. Alkalinity: While the estimates for alkalinity suggested a requirement of 2410 mg/l (as CaCO_3), actual demands established during the initial stabilization period were much less. It was found that the pH could be maintained above 7.0 by supplementing the enriched feed with only 260 mg/l NaHCO_3 (157 mg/l as CaCO_3). This is due, in part, to the significant stripping of CO_2 from solution under actual operating conditions.

Figure 4. Theoretical Effluent COD and Ammonia Nitrogen
as a Function of Mean Cell Residence Time

3. OPERATING PARAMETERS

Knowing the bacterial growth and substrate utilization coefficients for a particular waste under specified environmental conditions, Equation (11) may be used to relate effluent soluble substrate concentration to mean cell residence time. Using the coefficient data summarized in Table 5 for COD removal (domestic waste, skim milk) and nitrification, the relationship in Figure 4 results.

It is clear from Figure 4, that in order to insure viable heterotrophic and autotrophic populations during this laboratory investigation, a cell residence time of at least six days should be maintained. In a laboratory environment, it is generally more desirable to monitor and maintain a constant θ and X_v or X in an effort to realize θ^* . For the mixed treatment system of interest here, X_v can be described by a modification of Equation (27):

$$X_v = \frac{\theta}{\theta_c} X_r^o + \frac{S}{S^o} X_d^o + \frac{Y(S^o - S)}{1 + b\theta_c} (1 + (1 - f_d)b\theta_c) \theta_{cH} + \frac{Y(S^o - S)}{1 + b\theta_c} (1 + (1 - f_d)b\theta_c) \theta_{cA} \quad (24)$$

and recall that:

$$X = \frac{\theta}{\theta_c} X_{in}^o + X_v$$

where the subscripts H and A stand for heterotrophic and autotrophic, respectively. The autotrophic biomass is, however, only about four percent that of the heterotrophic, the inference being that the last term in Equation (24) can be dropped. Designing for a Mixed Liquor Suspended Solids (MLSS) of 4500 mg/l** a constant hydraulic detention time of 6.67 hours, and using the skim milk coefficients (conservative), Equations (11) and (23) lead to a θ_c of 7.5 days. These parameters are summarized in Table 6.

*Under constant influent and environmental conditions the growth rate will remain constant ($S^o \gg K_s$). When this situation is accompanied by efficient clarification, the amount of mixed liquor wasted to maintain the design MLSS will be constant and θ_c will, therefore, also remain constant.

** Assumptions: $X_a^o = X_i^o = 0$

$$X_r^o = 0.35 X_v^o$$

$$X_d^o = 0.65 X_v^o$$

Figure 7. Aeration Basin and Clarifier

4. BENCH SCALE SYSTEM

Figure 5 is a schematic of the laboratory system developed for continuous flow studies. The reactors were initially seeded with mixed liquor from the Panama City conventional activated sludge plant and subsequently maintained as summarized below.

Several afternoons each week 200 gallons of primary effluent were withdrawn just upstream from the Tyndall AFB STP trickling filters and immediately transported to the Environics Laboratory located approximately one mile from the plant. At this point the wastewater was transferred to five 151-liter (40-gallon) containers inside a refrigeration unit (4.4°C) adjacent to the laboratory. All raw feed was stored in this configuration until utilized as substrate base, but in no case did the storage time exceed four days.

The raw feed, having been enriched and supplemented in the feed tank, was pumped through a heat exchange (25°F) and then into the mixing chamber, illustrated in Figure 6. This chamber was designed such that two continuous feed toxicant concentrations could be evaluated simultaneously. As indicated, the center channel received only the supplemented feed solution, serving the control series of reactors. The 6-liter Plexiglas® aeration basins detailed in Figure 7 were supplied with humidified air passed through an activated carbon filter to affect excess dissolved oxygen and complete mixing. Sludge return from the 2-liter Pyrex® clarifiers was maintained using gravity induced draw-off and an in-line air pump.

5. EXPERIMENTAL MATRIX

The continuous feed studies were conducted over a wide range of fuel concentrations, specifically 20, 10, 6, 3, 1.0, and 0.5 mg/l. Four reactors were evaluated at each concentration in addition to four controls operated throughout the study. Because two concentrations could be evaluated simultaneously, a total of three runs were performed for each fuel. These have been designated 20/10, 6/3, and 1/.5 with the numbers referring to the target fuel concentrations.

Slug loading experiments were performed at concentrations of 250, 125, 50, and 25 mg/l (based on 6) on duplicate continuous flow reactors. These concentrations were realized by adding from 1 to 12 milliliters (ml) of stock fuel solutions directly to the aeration basin.

In the slug studies effluent characteristics were monitored for sufficient time to make inferences about process recovery. All reactors were allowed to achieve steady state as indicated by effluent COD and NO₃-N concentrations prior to initiating hydrazine feeds for any one particular evaluation. Table 7 summarizes the seeding/evaluation sequence employed.

6. ANALYTICAL PROCEDURES

a. General: Those parameters of interest included the major forms of nitrogen (NH_3 , organic, NO_3^-), COD, total and volatile suspended solids, HZ, MMH, UDMH and pH. Orthophosphate and alkalinity were monitored less frequently. All assays were performed in accordance with Standard Methods for the Examination of Water and Wastewater, 14th edition. Specific techniques are outlined in Table 8. Notable exceptions and comments are summarized below.

b. Hydrazine: The colorimetric method described by Watt and Chrisp (Reference 19) was used for all HZ and MMH assays. This procedure is based on a stable yellow color which develops upon addition of p-dimethyl-aminobenzaldehyde to dilute solutions of hydrazine. Absorbance was measured at 460 anometers (nm) using a Coleman 55 digital spectrophotometer.

UDMH determinations were accomplished using the colorimetric method outlined by Pinkerton, Lauer, Diamond, and Tamas (Reference 20). The procedure develops a colored solution using trisodium pentacyano-amino ferroate (TPF) and a disodium acid phosphate/citric acid buffer. During this investigation the recommended buffer concentrations were increased by a factor of 3.5 to increase sensitivity. It was also found that a wavelength of 495 anometers (nm) provided greater accuracy than the recommended 500 anometers (nm).

c. Schedule: Five days each week mixed liquor samples were collected and immediately analyzed for total and volatile suspended solids. Filtered effluent samples (Whatman #40) were used in the determination of NO_3^- -N, COD, and pH. Unfiltered aliquots of these same samples were

assayed for NH_4^+ -N and organic -N. Unfiltered influent samples were analyzed for these same parameters. Both influent and effluent were intermittently checked for orthophosphate, alkalinity, and suspended solids. Qualitative microscopic examinations of the mixed liquor were also conducted on an irregular basis throughout the investigation. Wasting was accomplished once daily directly from the aeration basin to realize the desired MLSS. During continuous flow hydrazine studies, influent fuel concentrations were assayed at least once daily from each reactor.

** Comparisons with Brucine method yielded good correlation.

SECTION IV

RESULTS - HYDRAZINE (HZ)

Neat hydrazine is a colorless liquid with a density of 1.000 gm/ml at 20°C. It is very soluble in water. Duplicate analyses of a 125 mg/l stock solution resulted in 0.23 mg COD/mg HZ and no detectable ammonia or organic nitrogen.

1. CONTINUOUS FEED STUDIES

a. HZ Degradation: Although it was the objective of this study to maintain stable hydrazine concentrations during each run, actual analyses showed that there was some variation. Figure 8 shows the measured HZ concentrations in the influent to the reactors. Each point represents the average of four reactors, and as can be seen, the percent variation was greater in the lower concentration studies. Experiments attempted at 1 mg/l actually represent exposure between 0.6 mg/l and 0.9 mg/l. Those designed for 0.5 mg/l were measured to be between 0.2 mg/l and 0.4 mg/l. The theoretical and measured average influent and effluent hydrazine concentrations for the continuous feed studies are summarized in Table 9. It is apparent that degradation of HZ occurs at all influent concentrations investigated. Because degradation by atmospheric oxidation was not observed in control studies where tap water was substituted for the activated sludge (see Figure 17, paragraph 2a, this section), the documented reductions in HZ are assumed to be the result of microbial metabolism.

b. COD: Table 10 summarizes the influent and control reactor effluent data for the continuous feed studies. While the mean influent values were very close to the target of 320 mg/l for all runs, the standard deviations suggest a wider than optimal range for individual values. Figure 9 shows the daily influent data as well as the mean effluent CODs from the four control reactors. As can be seen, effluent quality remained very stable in the controls despite influent COD fluctuations. These findings agree with data presented by Saheh and Gaudy (Reference 22) who have reported that recycle systems can handle a 200-percent step change in influent organic substrate concentration with only a small, short-lived disturbance in effluent quality. They have further stated that when a constant recycle rate is employed, as was the case in the present study, such step increases can be accommodated with little or no change in effluent quality. Note also that the data presented are for unfiltered samples. The standard deviations on the filtered influent CODs were consistently smaller.

Remaining COD in the clarifier effluent as a function of influent HZ concentration and time is shown in Figure 10. For the operating parameters in this study, a HZ concentration of approximately 3 mg/l causes no reduction in treatment efficiency. Concentrations above 10 mg/l result in the complete loss of COD removal capabilities within a few days.

Effluent organic nitrogen is related to effluent COD, as shown in Figure 11. Microscopic examinations of exposed activated sludge samples

verified that significant cell lysis was affected by HZ, releasing soluble organic nitrogen and other organics which contributed to soluble effluent COD as well.

c. Nitrification: The influent and control effluent nitrogen data collected over the continuous feed HZ studies are summarized in Table 11. Overall, 80-percent nitrification of influent TKN was achieved during these experiments. Effluent ammonia concentrations agreed well with those predicted based on the growth and substrate utilization coefficients discussed in Section III of this report. (Figure 4).

As for COD, the daily influent and control effluent parameters of interest have been graphically displayed in Figures 12 and 14 for comparison with daily effluent qualities in those reactors receiving HZ. The data in Figure 12 clearly indicates that while influent ammonia and TKN varied somewhat from day to day, effluent ammonia concentrations were consistently below 0.2 mg/l. From Figure 13 it is apparent that even low HZ concentrations (~ 3 mg/l) cause inhibition of nitrification. The nitrate data presented in Figure 15 agree well with the ammonia data. As effluent ammonia increases, effluent nitrate decreases. The combined NH_3 and NO_3 data suggest that HZ is definitely toxic to Nitrosomonas sp. in this range. Because the conversion of ammonia to nitrite is generally considered to be the rate limiting step in the oxidation scheme, no such inferences can be made with respect to Nitrobacter sp.

d. Suspended Solids: The suspended solids data for the control reactors are outlined in Table 12. Recall that, during the 20/10 and 6/3 runs, the high reactors (20 and 6 mg/l) were operated at an MLSS of 5600 mg/l while the low reactors (10 and 3 mg/l) were held at 4000 mg/l.

The MLSS response to HZ are summarized in Figure 16. As in Table 12, all values represent concentrations prior to wasting to the desired levels. Wasting was accomplished once daily if the MLSS concentration was above the target value. Both HZ and influent COD affected MLSS. Step increases in influent COD generally resulted in increased MLSS values as, for example, on day 2 of the 20/10 run. While HZ concentrations from 10 to 20 mg/l caused increased effluent organic nitrogen concentrations (Figure 11) and therefore effluent suspended solids, the majority of which were lysed cells (qualitative observation), the loss of solids was not of sufficient magnitude to decrease MLSS and hence θ_c significantly during any of the runs.

2. SLUG FEED STUDIES

a. HZ Degradation: Figure 17 is a plot of the ratio reactor HZ concentration (C) over the initial added HZ concentration (C_0) versus time. The initial drop in the control plot is due to the dilution effected by the clarifier volume. As in the continuous feed studies, there is significant degradation of the hydrazine even at an initial hydrazine concentration of 243 mg/l. Assuming exponential bacterial decay of the hydrazine, it is possible to calculate a bacterial decay constant (K) from Equation (25).

$$\ln C/C_0 = - \frac{1}{\theta_s} + Kt \quad (25)$$

C = HZ at time t (mg/l)

C_0 = HZ at time 0

θ_s = Total system (reactor plus clarifier) hydraulic detention time (HR) = 7.78 HR

t = Time (HR)

K = Bacterial Decay Constant (HR^{-1})

If hydrazine was not toxic to the activated sludge fauna, Equation (25) would predict that K would be independent of C_0 . This was not observed, as shown in Table 13 and in Figure 18, which is a plot of the calculated half-life ($t_{1/2}$) of hydrazine at each added concentration.

TABLE 13. BACTERIAL DECAY CONSTANTS FOR HZ

Initial HZ (mg/l)	K (HR^{-1})	Correlation Coefficient (R)
23	0.498	0.9730
44	0.353	0.9912
119	0.246	0.9914
243	0.160	0.9916

b. Acute Response: Influent parameters during the 8-hour acute response study are summarized in Table 14.

TABLE 14. SLUG LOAD RESPONSE INITIAL CONDITIONS (mg/l)

HZ		Influent			MLSS

Figure 17. HZ Degradation During HZ Slug Feed Experiments (Mean of Duplicates)

Figure 18. Calculated Half Life for HZ as a Function of Initial HZ Slug Concentration

(1) COD: Figure 19 shows that, as would be expected from the continuous feed studies, the high initial hydrazine concentrations caused an immediate decrease in treatment efficiency. Of the 146 mg/l COD in the effluent at one hour, only 33 mg/l can be attributed to HZ. The 243 mg/l samples were inadvertently lost because they exceeded the maximum value (400 mg/l) for the COD protocol employed. Although there was some apparent effect at all the concentrations tested, the reduction of treatment efficiency, as measured by COD removal, would be minor for slug doses which did not increase the concentration to above 44 mg/l N_2H_4 . Figure 20 clearly shows that effluent organic nitrogen concentrations were elevated from 0 to 6 times initial values depending on the HZ slug.

(2) Nitrification: The effect of HZ slug feeds on nitrification is shown in Figures 21 and 22. Even at 23 mg/l there is immediate inhibition. The nitrate decay rate is approximately equal to that expected for a completely mixed reactor with no influent nitrate, confirming that at all concentrations the oxidation of ammonia to nitrate has ceased.

c. Recovery: One of the objectives of this investigation was to document the time required to recover process efficiency following slug hydrazine exposures. The influent and control effluent COD and nitrogen data monitored throughout the recovery period are outlined in Figure 23.

(1) COD: Figure 24 illustrates that even for the 243 mg/l study there was significant recovery within 4 days and complete recovery within 6 days. Recovery from HZ concentrations below 44 mg/l was complete after approximately 3 days.

(2) Nitrification: Recovery of the nitrifying bacteria is slower than for the heterotrophs. In Figure 25 it can be seen that ammonia oxidation had not returned to normal until after 7 to 10 days. There appears to be an additional lag of from 1 to 8 days until a viable Nitrobacter sp. population is reestablished as indicated by Figure 26, suggesting that HZ is toxic to this species as well.

(3) Suspended Solids: As noted earlier, the slug doses of 243 mg/l and 119 mg/l produced significant cell lysis, the end result being increased solids in the effluent. Figure 27 indicates that at 243 mg/l the MLSS dropped to a low of approximately 2000 mg/l for about 4 days while those reactors receiving 119 mg/l HZ declined to approximately 3000 mg/l in this same time frame. Recovery at these high concentrations was not complete until 12 to 14 days post exposure. The 44 mg/l and 23 mg/l slug reactors were not significantly affected with respect to MLSS concentrations although effluent solids increased slightly for the first few days following introduction of the HZ.

SECTION V

RESULTS - MONOMETHYLHYDRAZINE (MMH)

Monomethylhydrazine is a colorless liquid with a density of 0.874 gm/ml at 20°C. It is very soluble in water. Duplicate analyses of a 125 mg/l stock solution resulted in 1.56 mg COD/mg MMH, 0.03 mg NH₃-N/ mg MMH, and no detectable organic nitrogen.

1. CONTINUOUS FEED STUDIES

a. MMH Degradation: Figure 28 shows the measured influent MMH concentrations during these studies. The theoretical and measured average influent and effluent MMH concentrations are summarized in Table 15.

As for HZ, control reactors with aerated tap water showed no MMH degradation over 8 hours. The percent reductions indicate microbial degradation or degradation catalyzed by the solids in the reactor. The low percent removal observed during the 0.5 mg/l study (60 percent) is attributed to certain operational problems. During the 1/0.5 run effluent COD concentrations in the 0.5 mg/l reactors rose significantly on day 3. Effluent organic-N values were not recorded on day 3 but were very high on day 4. COD, Organic-N, and NH₃-N values remained slightly elevated throughout the remainder of the study while MLSS concentrations declined. One of the four reactors began to bulk significantly during this period.* It was also noted that the effluent quality of the controls was below normal with respect to both COD removal and nitrification during this time period; one control began to bulk on day 4*. It should be pointed out that all of the effluent parameters were extremely sensitive to bulking conditions: either directly (COD, org-N), owing to the filtration protocol (Whatman #40), or indirectly (NH₃-N, NO₃-N), as a result of decreased Q_c . The above and the fact that the heterotrophic response seemed to be on the same order of magnitude as that for the autotrophs (uncharacteristic for these fuels), might suggest a transient hydraulic anomaly in reactors 5 to 12 as the cause for these observations. The reduced MMH degradation is assumed to be primarily a function of the decreased solids level.

Assuming that the average MMH degradation level at concentrations below 1 mg/l is approximately 90 percent and 50 percent at 3 to 6 mg/l, it is difficult to explain the 75-percent removal rate at 10 to 20 mg/l. No explanation is offered at this time.

b. COD: The influent and control reactor effluent data are given in Table 16. Figure 29 shows the daily influent data as well as the mean effluent CODs from the four control reactors. Effluent quality in these reactors was clearly very stable. The high influent COD on day 1 for the 20/10 appears to be due to an unrepresentative sample (suspended matter) as the filtered sample had a COD of only 298 mg/l.

* All effluent data from the 2 bulking reactors were ignored after day 4.

Overall	-	10.1	2.4	31.0	11.6	0.2	0.9	81

*Based on TKN conversion to NO₃-N

Effluent COD as a function of influent MMH concentration and time is shown in Figure 30. Effluent quality was affected for all concentrations except 0.9 mg/l. Increased DODs for the 0.5 mg/l run after day 1 are unexplainable when compared with the 0.9 mg/l data. Although pumping rates were checked on days 2 and 3, influent MMH concentrations were not quantified. It is possible that at some time during day 2 or day 3 a transient hydraulic anomaly caused elevated influent MMH concentrations which resulted in these high data points. This same trend was observed for organic nitrogen, as shown in Figure 31. A close correlation exists between effluent COD and organic nitrogen, as observed for HZ.

c. Nitrification: Influent and control effluent nitrogen data collected over the continuous feed MMH studies are outlined in Table 17. Overall, 81-percent nitrification of influent TKN was achieved.

The daily influent and control effluent parameters have been graphically displayed in Figures 32 and 34 for comparison with the data presented in Figure 33. Figure 33 indicates that the autotrophs are sensitive to MMH at concentrations above 0.5 mg/l. The rising $\text{NH}_3\text{-N}$ trend for the 0.5 mg/l study after the 5-day point can be attributed to the high influent TKN on that day (Figure 32). The nitrate data in Figures 34 and 35 support this argument because, if the increased effluent ammonia concentrations were the result of MMH inhibition, nitrate concentrations would be expected to decline. Indeed, nitrate levels significantly increased in the control reactors. The nitrogen data contradicts the theory that hydraulic anomalies were responsible for elevated COD and organic nitrogen concentrations in the 0.5 mg/l study. The 0.9 mg/l plots in Figures 30 and 35 clearly show that the autotrophs are inhibited at this MMH concentration while the heterotrophs are not. MMH addition should not be expected to adversely affect COD and organic nitrogen with a concurrent rise in effluent $\text{NO}_3\text{-N}$. There remains no basis for the reduced COD removal observed for 0.5 mg/l shown in Figure 30.

d. Suspended Solids: Table 18 summarizes the control suspended solids data. MLSS response to MMH is recorded in Figure 36. No difficulty was experienced in holding MLSS concentrations at the desired 4500 mg/l even though it was qualitatively observed that effluent suspended solids increased during MMH feeds. The same dispersed fine floc was present as for the HZ runs, indicating cell lysis rather than a bulking mechanism as the cause.

2. SLUG FEED STUDIES

a. MMH Degradation: Figure 37 clearly shows that MMH was degraded during the slug feed experiments. Using Equation (25) the bacterial decay constants in Table 19 were derived. Figure 38 is a plot of the calculated half life ($t_{1/2}$) for MMH at each initial concentration.

TABLE 19. BACTERIAL DECAY CONSTANTS FOR MMH

25	32	382	9.0	20.2	4510	78

*Wasted to 4500 mg/l prior to slug

(1) COD: Figure 39 shows that effluent COD is effected at all slug MMH concentrations except 32 mg/l. Figure 40 shows that the organic nitrogen response at 32 mg/l MMH is initially much greater than for the 110 mg/l and 68 mg/l doses. These data are not understood. It can be shown that at the one hour point, for the 273 mg/l slug, only 50 percent of the effluent COD was due to residual MMH in the reactor, indicating that cell lysis and/or metabolic inhibition had already occurred. This same data point in Figure 40 indicates that soluble organic nitrogen had been released in significant amounts at this time.

(2) Nitrification: The effect of MMH slug feeds on nitrification is shown in Figures 41 and 42. Even at 32 mg/l there is complete inhibition after 8 hours. The nitrate decay rate is somewhat faster than that predicted based solely on hydraulics. The scatter in the individual concentration plots also suggests that some interference which results in decreased NO₃-N is a function of MMH concentration. This interference could not be duplicated in distilled water solutions and is unexplained.

Figure 40. Acute Effluent Organic Nitrogen Response to Slug MMH Loads as a Function of Time (Mean of Duplicates)

Figure 41. Acute Effluent Ammonia Nitrogen Response to Slug MMH Loads as a Function of Time (Mean of Duplicates)

c. Recovery: The influent and control effluent COD and nitrogen data monitored throughout the recovery period are outlined in Figure 43.

(1) COD: Figure 44 illustrates that there was significant recovery within 3 days even for the 273 mg/l slug.

(2) Nitrification: Recovery of the nitrifying bacteria is slower than for the heterotrophs. In Figure 45, it can be seen that 12 to 16 days were required to return effluent ammonia levels to their pre-exposure level. Figure 46 is a plot of effluent nitrate recovery for the MMH study. As no control data was available from days 6 and 8 on for the 68/32 mg/l and 273/110 mg/l slugs, respectively, a plot of actual effluent $\text{NO}_3\text{-N}$ versus time for this period has been presented as an inset. While this does not represent recovery as well as the comparison with control effluent $\text{NO}_3\text{-N}$ (C/C_\star), the rising trend in nitrite oxidation is dramatic enough to make inferences about nitrate recovery. The data suggest that approximately 16 days are required for complete recovery. The lag observed in establishing a *Nitrobacter* sp population during the HZ study appears to have been reproduced in the MMH study although overall MMH recovery periods were longer by 4 to 6 days.

(3) Suspended Solids: The MLSS response to MMH as shown in Figure 47 was not as drastic as for comparable HZ concentrations even though the COD and organic nitrogen effects were similar in magnitude. MLSS values never dropped below 3200 mg/l, returning to normal levels in all cases after 4 days. The decline in MLSS for the 68 mg/l and 32 mg/l studies after day 7 is attributed to bulking in 3 out of the 4 reactors (10, 11, 12) and not MMH. The reason for the bulking in these specific reactors is not known but is assumed to be related to hydraulic anomalies as this problem was noted from time to time in different reactors (including controls) but generally not in all 12 at once.

SECTION VI

RESULTS - UNSYMMETRICAL DIETHYLHYDRAZINE (UDMH)

Unsymmetrical dimethylhydrazine is a colorless liquid with a density of 0.786 gm/ml at 20°C. It is very soluble in water. Duplicate analyses of a 125 mg/l stock solution resulted in 1.89 mg COD/mg UDMH, 0.15 mg $\text{NH}_3\text{-N}$ /mg UDMH, and no detectable organic nitrogen.

1. CONTINUOUS FEED STUDIES

a. UDMH Degradation: The influent UDMH data are shown in Figure 48 and indicate some variation about the target concentrations. Each point represents the average of 4 reactors. The influent and effluent data have been summarized in Table 21.

While degradation occurs at all concentrations investigated, it is interesting to note that the percent reductions are significantly lower than for neat hydrazine at comparable concentrations. This will be addressed in more detail in the next section.

b. COD: Table 22 summarizes the influent and control reactor effluent data for the continuous feed studies.

Figure 49 shows the daily influent data as well as the mean effluent CODs from the four control reactors. Remaining COD in the clarifier effluent as a function of influent UDMH concentration and time is shown in Figure 50. When compared with the control data, it would seem that the no effect UDMH concentration is approximately 5 mg/l. The response at 8.0 and 18.9 mg/l is essentially the same but less than that documented for HZ and MMH by a factor of two for comparable concentrations. It would also appear as if some degree of acclimation occurred as the effluent CODs exhibited a steady downward trend after day 2. This information is extremely interesting in light of the UDMH degradation data presented later. Although the toxic effects appear to be significantly less than that observed for HZ and MMH, UDMH is degraded at one-half the rate. This would suggest that UDMH was serving as an alternate carbon source to which the heterotrophic organisms may acclimate after 4 to 5 days. The HZ molecule is similar to that of ammonia, NH_3 , and it is theorized that HZ is taken into the cell by means of a like mechanism exhibiting its toxic effect once assimilated. This would account for the high degradation rate for HZ with high concurrent toxicity. The organic nitrogen data in Figure 51 also supports this argument as heterotrophic cell lysis, represented by effluent organic-N, was minimal.

c. Nitrification: The influent and control effluent nitrogen data collected over the continuous feed UDMH studies are presented in Table 24.

The daily influent and control effluent parameters have been graphically displayed in Figures 52 and 54 for comparison with the daily effluent qualities in those reactors receiving UDMH. From Figure 53, it is apparent that concentrations above approximately 1 mg/l cause inhibition of nitrification. The nitrate data presented in Figure 55 agree well with the ammonia data. The drop in effluent $\text{NO}_3\text{-N}$ on day 1 was observed in the control reactors (Figure 54) as well as for the 0.9 and 0.6 mg/l UDMH reactors. Unlike the heterotrophs, there appears to be no autotrophic acclimation to UDMH.

d. Suspended Solids: The suspended solids data for the control reactors are outlined in Table 23. Figure 56 summarizes all MLSS data.

TABLE 23. CONTROL MLSS DATA (mg/l)

<u>Study</u>	<u>Mean</u>	<u>σ</u>	<u>n</u>

2. SLUG FEED STUDIES

a. UDMH Degradation: Figure 57 clearly shows that UDMH was degraded during the slug feed experiments but at a lower rate than for HZ or MMH. The bacterial decay constants and half lives were computed as described earlier and are shown in Table 25 and Figure 58. These data agree well with the degradation theory proposed for the continuous feed results.

TABLE 25. BACTERIAL DECAY CONSTANTS FOR UDMH

25	22	314	11.6	21.5	5170	400

*Wasted to 4500 mg/l prior to slug

(1) COD: Figure 59 shows that effluent COD is not effected at slug doses below 74 mg/l. At the two hour point approximately 84 percent of the effluent COD was due to residual UDMH in the reactor. The remainder, 57 mg/l, representing no decline in substrate degradation. The organic nitrogen data in Figure 60 correlates well as it shows essentially no system upset even at 255 mg/l UDMH. However, at 3 hours some 90 mg/l of the effluent COD cannot be attributed to UDMH. Effluent organic nitrogen concentrations rose only slightly at this time, the implication being that the heterotrophic effects of slug UDMH doses in the range investigated are more related to inhibition than to toxicity and that these effects do not become manifest until approximately 3 hours post exposure. Concentrations below 74 mg/l UDMH produced no adverse effect.

Figure 57. UDMH Degradation During MMH Slug Feed Experiments (Mean of Duplicates)

Figure 58. Calculated Halflife for MMH as a Function of Initial UDMH Slug Concentration

Figure 59. Acute Effluent COD Response to Slug UDMH Loads as a Function of Time (Mean of Duplicates)

Figure 60. Acute Effluent Organic Nitrogen Response to Slug UDMH Loads as a Function of Time (Mean of Duplicates)

(2) Nitrification: The effect of UDMH slug feeds on nitrification is shown in Figures 61 and 62. Even at 22 mg/l, inhibition is complete after 8 hours. At 255 mg/l, it can be shown that inhibition is complete at 2 hours post exposure. The nitrate decay rate is essentially equal to that expected for a completely mixed reactor with no influent nitrate, indicating that at all concentrations the oxidation of ammonia to nitrate has ceased. Note that all of the plots are slightly above the predicted decay curve, an observation which suggests that inhibition was not instantaneous. If time zero is taken at 1 hour, the hydraulic decay and 255 mg/l curves are almost identical.

c. Recovery: The influent and control effluent COD and nitrogen data monitored throughout the recovery period are outlined in Figure 63.

(1) COD: Figure 64 indicates significant recovery after 48 hours for both the 255 mg/l and 128 mg/l slug feeds.

(2) Nitrification: Recovery of the nitrifying bacteria was again slower than for the heterotrophs. Figure 65 shows that 8 to 9 days were required to return to the pre-exposure ammonia oxidation levels. Effluent nitrate concentrations (Figure 66) are displayed as the slug reactor mean over the mean control value for all days except 0 to 9 during the 252 mg/l and 128 mg/l studies. As no control data was available, a plot of actual effluent $\text{NO}_3\text{-N}$ versus time has been presented as an inset. The nitrate recovery times match the ammonia recovery times very closely. This again implies that the autotrophic bacteria were inhibited rather than eliminated by the UDMH. No explanation can be offered with respect to the C/C_0 values in excess of unity for $\text{NH}_3\text{-N}$. Note that this same phenomena occurred during the MMH slug studies.

(3) Suspended Solids: The MLSS response to UDMH was minimal, as shown in Figure 67. The low value on day 7 for the 255 mg/l run was due to a low MLSS determination (2500 mg/l). This anomaly was attributed to unrepresentative sampling noting that the MLSS was 4470 mg/l the following day.

SECTION VII

SUMMARY

1. CONTINUOUS FEED STUDIES

It is apparent from the continuous feed studies that the three hydrazines could cause significant deterioration of an activated sludge plant if the concentration in the influent exceeded a few mg/l. For a reactor with hydraulic detention time (θ) of 9 hours and solids recycle ($\theta^C \sim 7$ days), the efficiency of organic carbon removal as measured by COD is seriously degraded when the influent concentration of hydrazine exceeds 10 mg/l. For UDMH and MMH, total failure is caused by concentrations of approximately 8 mg/l and 5 mg/l, respectively. In contrast to hydrazine and MMH, it appears that after 2 days the heterotrophic organisms begin to acclimate even to the ~ 20 mg/l UDMH feed concentration. Unfortunately, this test was terminated after 4 days so this conclusion should be made cautiously. Interpolating for the continuous feed studies reported here, the no effect level would be approximately 2 mg/l for hydrazine and 1 mg/l for MMH and UDMH.

Even if sufficient control could be maintained to insure dilution to these levels, complete degradation of the influent hydrazine would not be achieved. Only at the lowest hydrazine concentrations tested (< 1 mg/l) was the effluent feed concentration below detection limits. For MMH and UDMH, the maximum removal efficiency observed was 89 percent and 96 percent, respectively. Studies on the effect of these fuels on algae have established no effect concentrations of less than 0.001 mg/l for MMH and 1.56 mg/l for UDMH (Reference 24). To maintain these low effluent concentrations would require restricting influent concentrations to below 1 mg/l for the three fuels.

The influence of the hydrazines on nitrogen speciation is more pronounced than that found for carbon oxidation. Other nitrogen compounds shown to be powerful selective inhibitors of nitrification include thiourea, thioacetamide dithio-oxamide and cyanide. Inhibition of nitrification occurred at concentrations above 0.5 mg/l for MMH and 1 mg/l for the other fuels. These concentrations are significantly lower than the 10^{-3} M (32 mg/l) concentrations found by Yoshida and Alexander Reference 17) to inhibit Nitrosomonas. Indeed, they stated that ammonia oxidation still proceeded in the presence of 10^{-2} M (320 mg/l) hydrazine. This was indirectly inferred from data on the formation of hydroxylamine which could result from some other mechanism rather than ammonia oxidation. This selective effect could not be observed for hydrazine and MMH in the studies reported here. Both organisms appeared to be equally effected by comparison of the ammonia oxidation and nitrate formation data in Figure 13 and 15 and Figures 33 and 35. From Figures 53 and 55 it is possible to infer a less immediate effect on ammonia oxidation than nitrate formation; however, in the operation of an activated sludge plant, such information is of minor importance. The results shown in Figure 13 illustrate that in this study ammonia oxidation ceased or was severely reduced at hydrazine concentrations greater than 1 mg/l as reflected in increasing ammonia and decreasing nitrate concentrations in the reactor effluents. Maintaining a stable organic nitrogen concentration

proved difficult and so quantitative evaluation of the effect of the fuels on effluent ORG-N is difficult to ascertain. Qualitatively, removal of organic nitrogen closely parallels removal of COD. This is particularly evident in the UDMH studies which exhibit a much lesser disruption even at 20 mg/l, although from data on degradation of the three fuels (Tables 9, 15, and 21) the reduced toxicity cannot be attributed to lower equilibrium UDMH concentrations in the reactors. UDMH displayed the highest stability to degradation with an average reactor concentration of 12.6 mg/l compared to 6.1 mg/l for hydrazine and 3.7 mg/l for MMH for a nominal feed concentration of 20 mg/l. The percentage fuel degradation in the reactors can be estimated from the decay constants determined in the spill studies. Using a mass balance on the completely mixed flow reactor (CMFR) and assuming steady state conditions, the ratio of effluent concentrations to influent concentration can be calculated:

$$\frac{C}{C_0} = \frac{1}{1 + K\theta} \quad (26)$$

The percentage removals were calculated using a hydraulic detention time (θ) of 6.67 hours and the decay constants for the fuels at the lowest slug concentration, nominally 25 mg/l. The steady state percentage reductions (77 percent for hydrazine, 67 percent for MMH, and 39 percent for UDMH) compare favorably with the measured levels except for MMH. The low degradation of UDMH and the corresponding reduced toxicity implies that UDMH is taken up less by the heterotrophs and autotrophs than both hydrazine and MMH.

The impact on nitrification again reflects the correlation between percentage degradation of the fuel and toxicity. The reason for MMH displaying a more toxic effect to autotrophs than hydrazine is not apparent. This is the opposite trend shown in algae and fish batch studies. These studies, however, are biased by the different degradation rates of the fuels (References 23 and 24).

Mixed liquor suspended solids (MLSS) were relatively stable for all the experiments even though the reactors had quit functioning. It must be assumed that non-viable cells are a major portion of the remaining sludge.

2. SLUG FEED STUDIES

Although continuous addition of hydrazine to the sanitary sewage system is not recommended, it is important to know the effect of one time fuel doses on a treatment plant. Slug loads could result from an accidental spill that reaches the sanitary sewer system or the disposal of an improperly neutralized waste solution. Because of the short exposure, the effect of transient high concentrations of fuel would be expected to be less than a continuous exposure. Figures 17, 37, and 57 show the concentrations of hydrazines expected from strictly hydraulic decay (dilution) in a completely mixed flow reactor (CMFR) and the measured concentrations. It is apparent that there is uptake or break-down of the fuel which is not experienced in the absence of the biological solids.

NOTE: Volumes of fuel were calculated based on a density of 1.00 gm/ml (i.e. HZ). These values will be conservative for MMH and UDMH. The appropriate multiplication factors are:

MMH : 1.14
UDMH: 1.27

These bacterial decay constants are given in Tables 13, 19, and 25. The use of the term constant is a misnomer since, as shown for each fuel, the rate constant decreases with increasing fuel concentrations. Even though a simple first order reaction was assumed, this may not be the case and some complex reaction may be required to account for the disappearance of the fuel at a molecular level. The additional decay of the fuels observed in the reactors could be due to catalysis of the oxidation due to metals released from the stressed and lysed cells; however, without more rigorous experiments, it is not possible to speculate on a mechanism. It is important to note that if a spill is large enough to produce the concentrations studied here (25 to 250 mg/l) fuel will still remain in the plant effluent. Even for the lowest concentration used, ~25 mg/l, the effluent still contained hydrazine concentrations well above those found toxic to fish, algae, and other aquatic organisms.

Table 27 outlines the quantity of fuel required to produce concentrations from 1 to 250 mg/l for different size reactors (sewage treatment plant aeration basins). For a (1 MGD) plant with a hydraulic detention time of ~8 hours, typical of some AF installations, a 24.6-liter (6.5-gallon) spill from a F-16 emergency power unit would create a concentration of 14 mg/l in a completely mixed aeration basin. Since the basin is completely mixed, the immediate effluent concentration would also be 14 mg/l. In contrast to the continuous feed situation, however, an acute dose of this magnitude produces a minimal effect on plant operation. Figures 19, 39, and 59 present data on the influence of acute doses up to 273 mg/l on COD removal. The concentration which causes no significant effect is 74 mg/l for UDMH, 44 mg/l for hydrazine, and ~32 mg/l for MMH. Since both MMH and UDMH contribute COD, this must be accounted for to realistically compare the removal of COD from the substrate feed. For instance, 2 hours following a 225-mg/l UDMH slug, 295 mg/l of the 347 mg/l measured COD can be attributed to the fuel itself. Using semibatch reactor kinetics, it is possible to calculate the effluent COD given the influent COD, initial reactor COD, and the COD of the specific fuel using Equation (27).

$$\text{COD}_{\text{EFF}} = \text{COD}_{\text{INIT}} - \frac{1}{\theta} t + \text{COD}_{\text{INF}} \left(1 - e^{-\frac{1}{\theta} t} \right) \quad (27)$$

Comparing calculated effluent COD with measured COD in Figure 68 reveals a significant difference at the first hour. Measured CODs are only ~60 percent of the calculated value. For longer times, the calculated and measured values are remarkably close. The discrepancy at the short reaction times may be due to poor circulation between the clarifier and reactor. This same trend is apparent for effluent ammonia concentration, as shown in Figure 69. Figures 24, 44, and 64 illustrate that, for single exposures, COD removal returns to normal after 7 days for hydrazine and only 2 days for MMH and UDMH.

As in the continuous feed studies, the influence of slug fuel doses on the autotrophic organism is much more significant than on the heterotrophs. Ammonia oxidation is effected for all three fuels at the lowest concentrations tested. The decrease in nitrate exhibited by reactors dosed with hydrazine and UDMH is slightly slower than would be expected from simple wash-out from the reactor. The rapid decrease seen with MMH is unexplained.

Figure 68. COD Mass Balance for Slug UDMH Load

Figure 69. NH₃ Mass Balance for Slug UDMH Load

Attempts to document a reaction between MMH and NO_3^- or an interference with the nitrate probe were negative; nor is it likely that anaerobic denitrification could explain the rapid decrease seen for all 4 initial concentrations studied. A possible explanation might be that, under the conditions existing in the reactors, a catalyzed reaction between MMH and NO_3^- occurred. Unfortunately this was not evaluated while the reactors were operating.

SECTION VIII

CONCLUSIONS

Continuous Feed-All Fuels

- The use of activated sludge for continuous treatment of waste hydrazine fuel is not recommended. The rigid controls required to insure influent concentrations are maintained below the no effect level (1 mg/l) would not be practical.

- Discharges from pretreatment processes must be held to concentrations low enough to prevent values greater than 1 mg/l in the influent to Privately Owned Treatment Works (POTW) using activated sludge treatment to insure they are not adversely affected and that final fuel discharges into receiving waters are below environmentally significant levels.

Slug Loads-HZ

- Treatment plant efficiency, as measured by COD removal, is not seriously impaired for slug doses which result in aeration basin fuel concentrations up to 44 mg/l.
- COD recovery times for slug doses up to 243 mg/l are on the order of 4 to 5 days.
- Nitrification ceased at slug doses above 23 mg/l. The no effect concentration with respect to ammonia oxidation is between 1 to 23 mg/l.
- Ammonia recovery times for slug doses up to 243 mg/l are on the order of 7 to 10 days.

Slug Loads-MMH

- Treatment plant efficiency, as measured by COD removal, is not seriously impaired for slug doses which result in aeration basin MMH concentrations up to 32 mg/l.
- COD recovery times for slug doses up to 273 mg/l are on the order of 2 to 3 days.
- Nitrification ceased at slug doses above 32 mg/l. The no effect concentration with respect to ammonia oxidation is between 1 to 32 mg/l.
- Ammonia recovery times for slug doses up to 273 mg/l are on the order of 12 to 16 days.

Slug Loads-UDMH

- Treatment plant efficiency, as measured by COD removal, is not seriously impaired for slug doses which result in aeration basin UDMH concentrations up to 74 mg/l.
- COD recovery times for slug doses up to 255 mg/l are on the order of 2 to 3 days.

- Nitrification ceased at slug doses above 32 mg/l. The no effect concentration with respect to ammonia oxidation is between 1 to 22 mg/l.
- Ammonia recovery times for slug doses up to 255 mg/l are on the order of 8 to 12 days.

APPENDIX A

STOICHIOMETRY

A. General: The stoichiometric relationship developed by McCarty (Reference 6) is as follows:

$$R = R_d - f_e R_a - f_s R_c \quad (A-1)$$

R = overall reaction

R_d = half reaction for electron donor

R_a = half reaction for electron acceptor

R_c = half reaction for cell synthesis

f_e = fraction of e^- donor used for energy

f_s = fraction of e^- donor used for synthesis

where: $f_e + f_s = 1$.

In suspended growth systems, f_e and f_s are a function of cellular yield and the organism decay rate, the latter being a function of solids retention time. Using the classical growth equation for microorganisms and mass balance relationships for a suspended growth system, McCarty developed the following relationship:

$$f_s = a_e \left(1 - \frac{f_d b \theta_c}{1 + b \theta_c} \right) \quad (A-2)$$

where: a_e = cell yield coefficient expressed as equivalents of cells per equivalent^e of donor consumed (Figure A-1). a_e and b can be estimated from kinetic studies for a particular waste or from thermodynamic considerations. Oftentimes values are assumed based on previous work with similar wastes. The fraction f_d is most often assumed to be 0.8 for both aerobic and anaerobic organisms (Reference 1). Thermodynamic relationships, as reported by McCarty (Reference 6), are given by Equations (A-3) and (A-4).

$$a_e = \frac{1}{1 + A} \quad (A-3)$$

$$A = - \frac{\Delta G_p / k^m + \Delta G_n / k + 7.5}{k \Delta G_r} \quad (A-4)$$

ΔG_p = energy required to convert cell carbon source to an intermediate stage

$$= \Delta G^0(w)_d + 8.54$$

= 27.22 Kcal for inorganic e^- donors

$\Delta G^\circ(w)_d$ = free energy per mole of electrons for donor half reaction.

m = +1 if ΔG_p is >0 , -1 if <0

$$\Delta G_r = \Delta G^\circ(w)_d - \Delta G^\circ(w)_a$$

$\Delta G^\circ(w)_a$ = free energy per mole of electrons for acceptor half reaction.

k = efficiency of energy transfer for bacterial growth, ranging from 0.4 - 0.7.

ΔG_n = energy required to convert the nitrogen source for cell synthesis to NH_3 .

B. Heterotrophic Reactions: Using the data presented in Tables 1 and 2 and McCarty's procedure for constructing empirical formulations based on electron equivalent fractions of each component in the waste (Appendix B), the following relationship was developed for the enriched primary effluent and has been taken to represent the heterotrophic donor half reaction, R_d . The balanced equation has been normalized to 1 electron equivalent:

(A-5)

* $\Delta G^\circ(w) = -7.9$ Kcal/ e^- equivalent

The electron acceptor is oxygen; thus R_a is:

* $\Delta G^\circ(w) = 18.675$ Kcal/ e^- equivalent

Assuming an empirical formula for aerobic bacterial protoplasm (Reference 8) and noting that ammonia serves as the nitrogen source, R_c becomes:

C. Autotrophic Reactions: The following half reaction applies when NH_4^+ serves as the electron donor.

$$\Delta G^\circ(w) = 8.245$$

The reactions R_a and R_c are the same as for the heterotrophic situation.

*Reactants and products at unit activity except $H^+ = 10^{-7}$

D. Yield Coefficients: The bacterial yield coefficient, Y , expressed as grams cells/gram substrate removed may be estimated by writing the overall reaction, R , for the condition $\theta_c = 0$ (reference Figure A-1). The substrate of interest in the autotrophic reaction is NH_4^+-N which is amenable to direct measurement. However, since this is not the case for the heterotrophic substrate, it becomes advantageous to develop a relationship between organic substrate concentration and a standard parameter such as COD.

1. COD: The theoretical chemical oxygen demand for the supplemented feed solution may be calculated from the empirical formulation, thus:

On a molar basis, 1 mole donor \equiv 2008 gm COD. Based on a total organic fraction of 223 mg/l in the enriched feed (118.7 mg carbohydrate + 37.3 mg protein + 16.9 mg fat + 50 mg l^o effluent (measured value), a value of 433 mg/l COD results. Actual analyses of the primary effluent yielded 100 mg COD/50 mg yss/l which is, in fact, equal to the value predicted from the empirical formula $\text{C}_{10}\text{H}_{19}\text{O}_3\text{N}$ used in constructing the donor half reaction. The composite Slender[®] formulation, $\text{C}_{42}\text{H}_{71}\text{O}_{16}\text{N}_6$, does, however, yield a value 29 percent higher (286,000 mg/l) than that determined experimentally.

2. Heterotrophic Y: Assuming a k value of 0.6 (Reference 6) and employing $\Delta G^\circ(w)$ values developed in paragraph B, Equations (A-3) and (A-4) are used to find that $a_e = 0.65$. If $f_d = 0.8$, it follows from Equation (A-2) that $f_s = a_e$ and therefore $f_e = 0.35$. Substituting into Equation (A-1) yields the following relationship for R .

(A-10)

From the above coefficients and those relationships derived from equation (A-9) Y is 0.46 gm cells/gm COD removed. This value compares well with values reported in the literature for similar wastes (Reference 5).

3. Autotrophic Y: Again a_e may be calculated from thermodynamic considerations assuming $k = 0.6$. Thus, when $\theta_c = 0$; $a_e = 0.11$, $f_s = 0.11$, and $f_e = 0.89$.

The overall autotrophic reaction is constructed and used to estimate Y on a gram cells/gram NH_4^+-N removed basis.

(A-11)

$$Y = 0.34 \text{ gm cells/gm } \text{NH}_4^+-\text{N}$$

E. Supplemental Requirements: As discussed in paragraph A, f , f_s , and hence R , under actual operating conditions, are a function of \bar{S} , f_s^s , and θ_c . By writing balanced Stoichiometric reactions as a function of θ_c (Constant b , f_c), it can be shown that oxygen and alkalinity demands increase with increasing cell residence times. The advantages of approaching such an extended aeration system are lower observed yields ($Y_{OBS} = Y/(1+b\theta_c)$), effluent soluble substrate concentrations, and nutrient requirements.

1. Nutrients: In the interest of making conservative estimates the worst case was considered for the desired influent substrate concentrations, i.e., maximum yield ($\theta_c = 0$) and complete substrate utilization ($S^e = 0$). The assumption indicates that Equations (A-10) and (A-12) should be used to estimate maximum yield nitrogen and phosphorous requirements.

a. Nitrogen:

(1) Heterotrophic: Using the appropriate stoichiometric Equation (A-10), it is clear that one mole of donor requires 1.2 moles of NH_4-N for complete oxidation to occur. Based on an influent donor mass of 223 mg/l (organic fraction), it can be shown that a nitrogen requirement of 3.2 mg/l exists, the theoretical organic nitrogen supplied by the donor being 160 mg/l. Note that rule-of-thumb estimates are often made, based on the same yield and utilization assumptions employed here, assuming the typical aerobic cell contains 12-percent nitrogen. In this case, the resultant 17.6 mg/l value compares well with the stoichiometric total of 19.2 mg/l. Referring to Table 1, it is seen that approximately 12.7 mg/l of inorganic nitrogen is present in the raw feed solution. While this should provide an adequate excess of nitrogen, an additional 4.7 mg/l urea-N was routinely added to insure nitrogen was not limiting.

(2) Autotrophic: Considering all sources, the total organic and inorganic nitrogen in the described system is approximately 33.4 mg/l*. Of this, 19.2 mg/l is required for heterotrophic synthesis, the remainder, 14.2 mg/l, being available for nitrification. This total value agrees well with the average Kjeldahl nitrogen (29.8 mg/l) in the supplemented feed which was monitored throughout the study.

b. Phosphorous: As stated earlier, the phosphorous requirement is generally considered to be about 1/5 that of nitrogen. This rule of thumb assumes the typical aerobic cell contains approximately 2-percent phosphorous. In lieu of stoichiometry which includes a phosphorous component, this information, again based on maximum yield and complete substrate utilization, may be used to estimate the phosphorous demands.

- * 1° Effluent inorganic-N: 12.7 mg/l
 Electron donor organic-N: 16.0 mg/l; based on empirical formulation.
 Supplemental organic-N: 4.7 mg/l UREA-N

(1) Heterotrophic: Using a yield coefficient of 0.46 and an influent substrate concentration of 320 mg/l as CO₂, the resultant phosphorous requirement is 2.9 mg/l.

(2) Autotrophic: The autotrophic demand for phosphorous is expected to be low. Using the appropriate values, the calculations indicate a demand of 0.10 mg/l-P.

2. Oxygen and alkalinity: Conservative estimates of oxygen and alkalinity requirements were made based on a mean cell residence time of 20 days. The appropriate stoichiometry is summarized below.

HETEROTROPHIC: $a_e = 0.65$ $f_s = 0.39$, $f_e = 0.61$

AUTOTROPHIC: $a_e = 0.11$ $f_s = 0.066$, $f_e = 0.934$

The above relationships lead to the requirements outlined in Table A-1, assuming complete substrate utilization.

Figure A-1. Fraction of Electron Donor Used for Energy, f_e , and for Synthesis, f_s , as a Function of θ_c . A_e is the Maximum Cell Yield Coefficient on an Equivalent Basis

TABLE A-1. OXYGEN AND ALKALINITY REQUIREMENTS $\theta_c = 20$ DAYS

	Design S^0	O_2 gm/DAY	Alkalinity mg/l as $CaCO_3$
Heterotrophic	320 mg/l COD	4.20	2260*
Autotrophic	15 mg/l NH_4^+-N	1.35	150**
Total		5.55	2410

* Based on Carbonic Acid Equilibria, $pH \geq 7.0$ (Appendix C) and HCO_3^- requirements for synthesis.

** Assumed 10 times the NH_4^+-N to be oxidized (Reference 9).

APPENDIX B

EMPIRICAL FORMULATIONS

Raw Feed

1° EFF (Domestic Sewage) $1/50 \text{ C}_{10}\text{H}_{19}\text{O}_3\text{N}$

50 mg/l vss (measured value)

APPENDIX C

CALCULATION OF ALKALINITY REQUIREMENT FOR HETEROTROPHIC REACTION

$$pH = 6.4 + \log \frac{HCO_3^-}{H_2CO_3^*} \quad pK_1 = 6.4$$

$$\text{where } H_2CO_3^* = CO_2(aq) + HCO_3^-$$

$$\text{Assume } H_2CO_3 \ll CO_2(aq) \quad \text{i.e. } H_2CO_3^* \equiv CO_2(aq)$$

Desire pH > 7.0

$$\log \frac{HCO_3^-}{H_2CO_3^*} = \log \frac{HCO_3^-}{CO_2(aq)} \geq 0.6$$

For each mole of waste 34.5 moles CO_2 produced assume worst case, i.e.,

all CO_2 becomes $CO_2(aq)$

$$\log \frac{HCO_3^-}{34.5} \geq 0.6$$

$$\frac{HCO_3^-}{34.5} \geq 3.98$$

$$HCO_3^- \geq 137.3 \text{ moles}$$

In addition: HCO_3^- is destroyed to produce cellular matter, i.e., 4.9

moles per the stoichiometry $HCO_3^- \geq 142 \text{ moles}$

$$\frac{142 \text{ moles } HCO_3^-}{1 \text{ mole waste}} \times \frac{1 \text{ mole } C_aCO_3}{1 \text{ mole } HCO_3^-} \times \frac{100 \text{ gm } C_aCO_3}{1 \text{ mole } C_aCO_3} = 14200 \text{ gm } C_aCO_3/\text{mole waste}$$

$$(320 \text{ mg COD})/l \times \frac{1 \text{ mole waste}}{2008 \text{ gm COD}} \times \frac{14200 \text{ gm } C_aCO_3}{\text{mole waste}} = 2260 \text{ mg/l as } C_aCO_3$$
